ABSTRACT The yeast *Yarrowia lipolytica* is a potent accumulator of lipids, and lipogenesis in this organism can be influenced by a variety of factors, such as genetics and environmental conditions. Using a multifactorial study, we elucidated the effects of both genetic and environmental factors on regulation of lipogenesis in *Y. lipolytica* and identified how two opposite regulatory states both result in lipid accumulation. This study involved comparison of a strain overexpressing diacylglycerol acyltransferase (*DGA1*) with a control strain grown under either nitrogen or carbon limitation conditions. A strong correlation was observed between the responses on the transcript and protein levels. Combination of *DGA1* overexpression with nitrogen limitation resulted in a high level of lipid accumulation accompanied by downregulation of several amino acid biosynthetic pathways, including that of leucine in particular, and these changes were further correlated with a decrease in metabolic fluxes. This downregulation was supported by the measured decrease in the level of 2-isopropylmalate, an intermediate of leucine biosynthesis. Combining the multi-omics data with putative transcription factor binding motifs uncovered a contradictory role for TORC1 in controlling lipid accumulation, likely mediated through 2-isopropylmalate and a Leu3-like transcription factor.

IMPORTANCE The ubiquitous metabolism of lipids involves refined regulation, and an enriched understanding of this regulation would have wide implications. Various factors can influence lipid metabolism, including the environment and genetics. We demonstrated, using a multi-omics and multifactorial experimental setup, that multiple factors affect lipid accumulation in the yeast *Yarrowia lipolytica*. Using integrative analysis, we identified novel interactions between nutrient restriction and genetic factors involving regulators that are highly conserved among eukaryotes. Given that lipid metabolism is involved in many diseases but is also vital to the development of microbial cell factories that can provide us with sustainable fuels and oleochemicals, we envision that our report introduces foundational work to further unravel the regulation of lipid accumulation in eukaryal cells.

KEYWORDS biofuels, biotechnology, metabolic engineering, systems biology, yeast

The yeast *Yarrowia lipolytica* has been identified as a promising microbial cell factory for the production of biofuels and oleochemicals (1), and while metabolic engineering approaches have been employed to increase its lipid production (2–4), how its lipid metabolism is regulated remains largely unknown. Understanding the regulation

^aData represent dilution rates during the chemostat stage.

^bData were determined from the exponential phase during the batch stage.

^cData were obtained by subtracting the measured lipid concentration as depicted in Fig. S1 in the supplemental material. Data are means (SD) of results from three independent chemostats. r_{Gluc} (mmol gDW⁻¹ h⁻¹), glucose uptake rate in millimoles per gram dry weight per hour; r_{O_2} , oxygen uptake rate; r_{CO_2} , CO₂ excretion rate; RQ, respiratory quotient; Y_{sx} , biomass yield.

of lipid metabolism in *Y. lipolytica* is critical for the further development of this yeast into a versatile and robust microbial cell factory. Moreover, knowledge concerning the regulation of its lipid metabolism will allow further harnessing of *Y. lipolytica*'s potential by surveying the full lipogenesis landscape (5). There have been a few studies on the regulation of *Y. lipolytica* lipid metabolism during nitrogen limitation (N-*lim*) (6) that monitored transcriptional changes during a shift from biomass production to lipid accumulation (7) and that have identified roles for single regulators such as Mga2 (5), Snf1 (8), Mig1 (9), and TORC1 (4). To get a more complete picture, we set out to study regulation of *Y. lipolytica* lipogenesis at the genome level using chemostat cultures.

Similarly, it has been shown that lipid accumulation can be influenced by various factors, referred to as the lipogenesis landscape of *Y. lipolytica* (5). We focused on two categories of factors, environmental and genetic, by comparing the results of *Y. lipolytica* cultivation performed under conditions of either nitrogen or carbon limitation using two different strains: a diacylglycerol acyltransferase (DGA)-overexpressing strain with high lipid production and a control strain. *Y. lipolytica* has two DGA genes, in contrast to *Saccharomyces cerevisiae*, which has only one such gene, and both overexpression of *DGA1* and overexpression of *DGA2* increase lipid accumulation (2, 10). From transcriptome analysis of a *DGA1* overexpression strain, it has been postulated that this strain redirects carbon flux from amino acid metabolism toward lipogenesis during lipid accumulation (11). However, transcriptional responses are not necessarily translated into functional changes on the level of proteins and metabolic fluxes. We therefore set out to advance our understanding of the regulation of lipid metabolism by integrating changes in the levels of transcripts with changes in protein levels, metabolic fluxes, and metabolite concentrations. Here we identified important roles for key regulators that are highly conserved across eukaryotes.

RESULTS

Phenotypic changes during chemostat cultivations. A *DGA1*-overexpressing strain and a control strain were both exposed to nitrogen or carbon limitation conditions using chemostat cultivations operated at a dilution rate of about 0.05 h⁻¹, which is roughly 25% of the maximum growth rate (Table 1). For each condition, we performed biological experiments in triplicate.

Both the genetic and environmental factors, i.e., nutrient limitation and *DGA1* overexpression, had major effects on the physiology of the yeast as determined by its lipid content (see Fig. S1 in the supplemental material), while other physiological parameters, e.g., the specific glucose uptake rate, remained largely unchanged (Table 1). Total lipid accumulation was not significantly induced by *DGA1* overexpression alone or by nitrogen limitation alone; such induction was seen only when the two

factors occurred together (Fig. S1A). Several different lipid classes contributed to the total lipid accumulation, albeit *DGA1* catalyzes only the last step of triacylglycerol biosynthesis (Fig. S1B). Regardless, this supports previous findings where overexpression of *DGA1* had been identified as a promising strategy to increase lipid production in *Y. lipolytica* (2).

Transcriptional changes. To establish the relative levels of the transcripts, samples were taken from the chemostat cultivations and analyzed by RNAseq, and normalized counts were used for relative quantifications. The multifactorial design of the study allowed separation of the contributions of each individual factor to the expression level. A general linear model was constructed describing the expression level based on the following factors: (i) baseline expression; (ii) expression due to *DGA1* overexpression; (iii) expression due to nitrogen limitation; and (iv) expression due to an interaction between *DGA1* overexpression and nitrogen limitation ($DGA1 \times N\text{-}lim$). While nitrogen limitation had the largest effect on the differential expression of transcripts, with almost a sixth of the genes being differentially expressed (adjusted $P < 0.05$), the overexpression of *DGA1* and $DGA1 \times N\text{-}lim$ interaction also resulted in large transcriptional changes (Fig. 1A; see also Data Set S1 in the supplemental material).

Gene-set enrichment analysis was performed to identify the systemic response to each of the three factors. The effect of nitrogen limitation was dominated by a downregulation of beta-oxidation, transmembrane transporter, and transcription factors (Fig. 1B), with many of the genes downregulated significantly (adjusted $P < 0.05$). These results are shown to be more coherent by examination from a different perspective: glucose limitation results in upregulation of the aforementioned gene sets. The restricted availability of carbon triggers the cells to increase expression of transmembrane glucose transporters and to scavenge carbon from storage lipids by upregulating beta-oxidation. The upregulation of ergosterol biosynthesis upon nitrogen limitation is striking. In *Y. lipolytica*, lipids accumulate in lipid droplets that contain triacylglycerol and sterol esters; however, the highest lipid accumulation was observed only when nitrogen limitation occurred in combination with *DGA1* overexpression (Fig. S1).

Overexpression of *DGA1* resulted in an upregulation of genes associated with various GO terms related to ribosomes and translation (Fig. 1B), although the enrichment of these GO terms occurs mainly through the general upward drift of their constituent genes and, to a lesser extent, as a consequence of highly significantly changing transcript levels. While these changes hint at an increased level of activity of TORC1 (12), this effect is not very strong, and it is unclear how *DGA1* overexpression would activate TORC1. In nitrogen-limited shake-flask cultivations of wild-type (WT) *Y. lipolytica* (6), the ribosome was identified as significantly downregulated, and inhibition of translation with cycloheximide resulted in moderately increased lipid accumulation. In our experiments, however, it was not *DGA1* overexpression itself that provoked the largest phenotypic change but, rather, the combination of *DGA1* overexpression and nitrogen restriction that resulted in the highest lipid accumulation (Fig. S1A).

The transcriptional changes due to the $DGA1 \times N\text{-}lim$ factor were dominated by an upregulation of autophagy and a downregulation of amino acid biosynthesis (Fig. 1B). The strong upregulation of autophagy genes such as *ATG8* (Fig. 1C), together with an upregulation of genes involved in allantoin degradation (Data Set S1), suggests activation by the Gln3 transcription factor (13). During nitrogen limitation, amino acid biosynthesis is upregulated, while additional overexpression of *DGA1* results in repression (Fig. 1C; Fig. S2), indicating that Gcn4 is involved in its regulation (14).

Identification of transcription factor binding motifs. The expression dynamics described above raised questions concerning whether common transcription factors are involved in regulating the observed gene expression. To rationally elucidate this, the relative contributions of the three factors were ranked and the differentially expressed genes (adjusted $P < 0.01$) with the same order of factor contributions were grouped together (Fig. 2A).

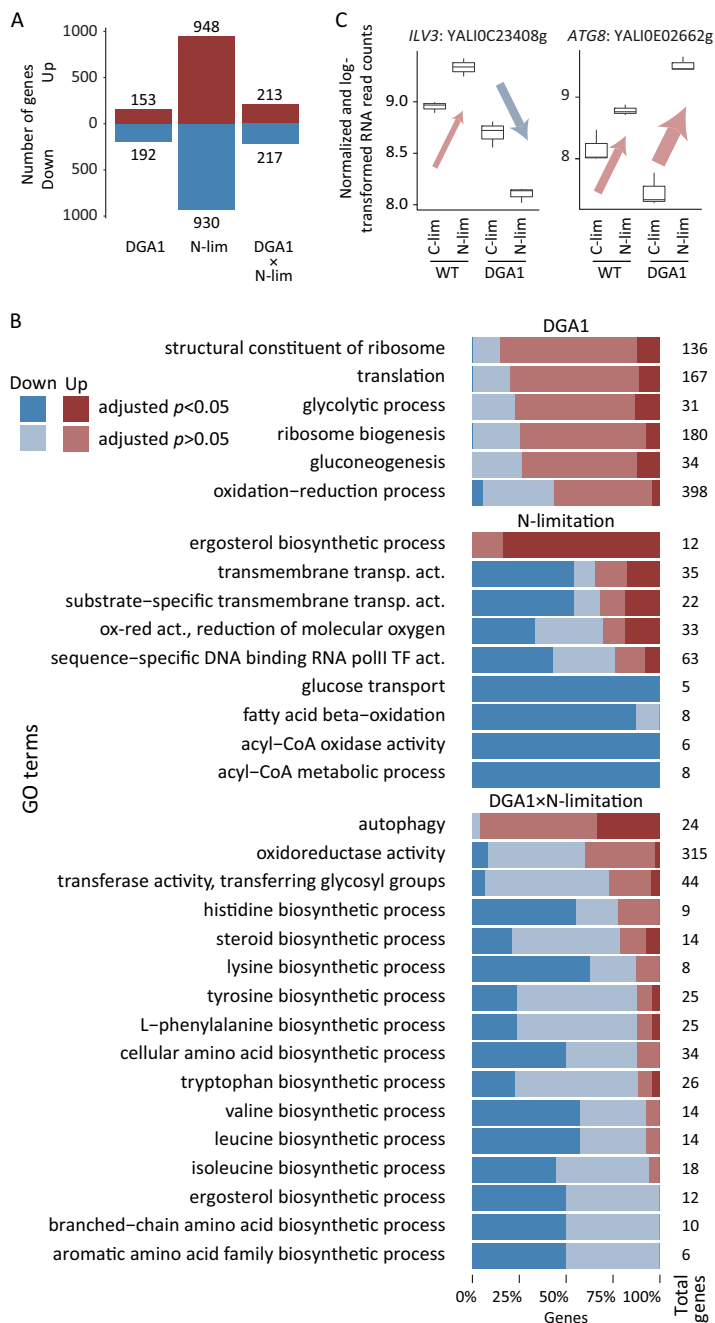

FIG 1 Consensus gene-set analysis using differential RNA expression according to a general linear model. (A) Overview of number of genes whose expression values were significantly (adjusted $P < 0.05$) influenced by *DGA1* overexpression (DGA1), nitrogen limitation (N-lim), or the $DGA1 \times N\text{-lim}$ interaction. (B) GO term enrichment analysis. For each significantly changed GO term (rank score of ≤ 5), the direction and significance of the changes in RNA levels of their constitutive genes are shown, together with the total number of genes within each GO term. ox-red, oxidation-reduction; polII, polymerase II; TF, transcription factor; transp. act., transporter activity. (C) Expression profiles of *ILV3*, involved in leucine biosynthesis, and *ATG8*, involved in autophagy, exemplifying the factorial effects. acyl-CoA, acyl-coenzyme A.

The promoter regions of each group of genes were queried for overrepresentation of motifs using DREME (15). From the same genes, overrepresentations of GO terms were identified with gene-set enrichment analysis. This revealed the involvement of several transcription factors orchestrating the expressional changes (Fig. 2B). For instance, motif A is seemingly involved in the upregulation of genes upon nitrogen

FIG 2 Enrichments of GO terms and transcription-factor binding motifs from genes with similar regulatory responses. (A) For each differentially expressed gene (adjusted $P < 0.01$), the relative contributions of the three factors (D, *DGA1* overexpression; N, nitrogen limitation; D×N, interaction of *DGA1* overexpression and nitrogen limitation) were ranked. The genes with the same order of factor contributions were subsequently clustered together (the number of genes per cluster is indicated). For example, for genes in group 4 (e.g., *ILV3*; see Fig. 1C), nitrogen limitation positively affects transcript levels, while D×N has a negative effect. *DGA1* overexpression by itself has an effect that is between those of the other two factors. (B) For each cluster, (i) the GO term enrichment (redundant terms removed by manual curation) and (ii) the motifs found by DREME (15), their E value, and *S. cerevisiae* transcription factors with similar binding motifs, as identified with Tomtom (31), are indicated.

limitation, while a further upregulation is observed when *DGA1* is overexpressed (group 1). Genes that show this behavior are enriched for involvement in autophagy. Notably, Mig1-like motifs (D and H) were identified in genes strongly downregulated upon nitrogen limitation. These genes are, among others, enriched for beta-oxidation, corroborating previous identifications of this motif from batch fermentations (6). Downregulation of amino acid biosynthesis under conditions of the *DGA1* × *N-lim* interaction (Fig. 1C; Fig. 2A, group 4) was potentially regulated through transcription factors with motifs (E and G) that bear resemblance to *S. cerevisiae* Gcn4 and Leu3 motifs. Contrastingly, Gln3-like motifs B and F were also found in group 2, where the *DGA1* × *N-lim* interaction had very little effect on the transcript levels, while nitrogen limitation had a strong positive effect. While this agrees with the strong upregulation of genes involved in autophagy and allantoin degradation, motif A has an additional positive impact on genes involved in autophagy upon *DGA1* × *N-lim* interaction (Fig. 1C).

Correlating transcript and protein levels. Changes in transcript levels can be interpreted as representing attempts to adapt to changing conditions, especially if these changes are orchestrated through shared transcription factors. However, changes in transcripts are not necessarily translated into changes in the levels of proteins. We therefore performed relative quantifications of proteins using the accurate mass and time (AMT) tag proteomics approach (16). Normalized peptide abundances obtained

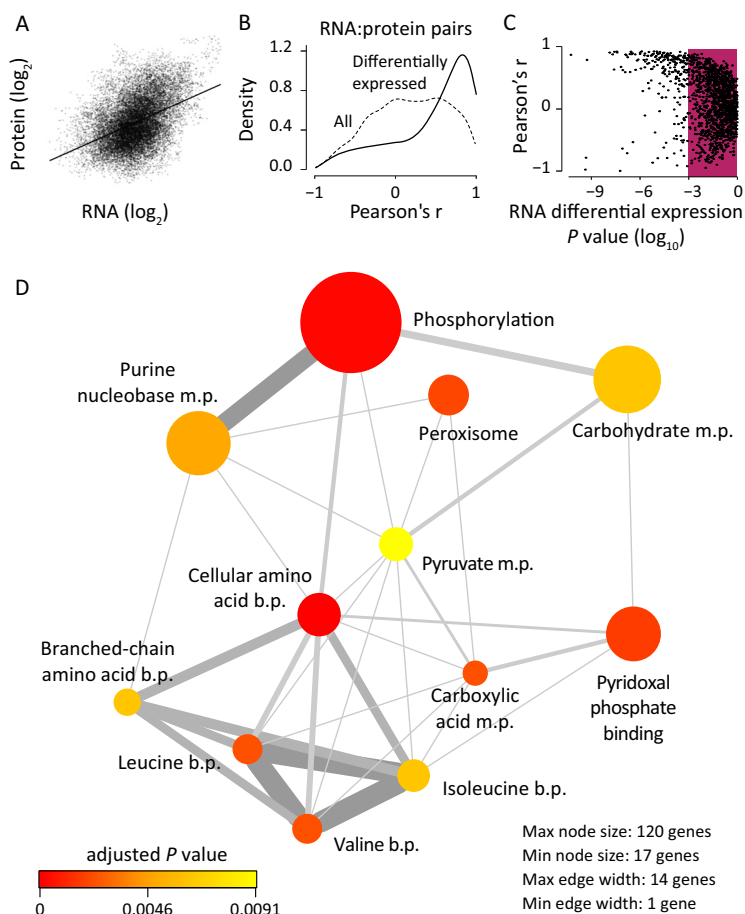

FIG 3 Correlation of log-normalized RNAseq read counts with log-normalized protein counts. (A) All measured RNA and protein counts combined in one comparison, with poor correlation observed. (B) Density plot of Pearson's r for all RNA-protein pairs (dotted line) and for only those RNA-protein pairs that showed differential expression at the level of RNA (adjusted $P < 0.01$; solid line). (C) Representation of the correlations of both the genes that were not significantly changed (in red box) and the genes whose transcripts were found to have changed in comparisons of all chemostats (adjusted $P < 0.01$). (D) Network plot of enriched GO terms in the highly correlated gene pairs ($P < 0.01$). The size of the node represents the number of genes within the GO term. The node's color represents the adjusted P value. The thickness of the edge indicates the number of genes overlapping two GO terms. m.p., metabolic process; b.p., biosynthetic process.

from the proteomics analysis were subsequently compared with normalized read counts obtained from RNAseq. To increase the confidence of the correlation between protein and transcripts, we focused only on the genes for which data were obtained from all 12 samples by both RNAseq and proteomics. This subset consisted of 1,516 genes, corresponding to 21.1% of the 7,170 genes annotated in the *Y. lipolytica* genome.

The correlation between all transcript-protein pairs was low (Pearson's r , 0.426) (Fig. 3A). This would be expected due to the differences in the translation rates for each protein (reviewed in reference 17), while low correlations are also expected for non-differentially expressed genes. Instead, when each transcript was correlated with its corresponding protein across conditions, the correlation over all 12 experiments was moderately enriched for positive correlations between transcript and protein (Fig. 3B). Separating 444 differentially expressed transcript-protein pairs (selected from the general linear model at the transcript level, adjusted $P < 0.01$; Data Set S1) resulted in a strong enrichment for positive correlation (Fig. 3B; Data Set S2). Additionally, there seems to be a trend toward stronger correlations for genes with a greater level of significant differential expression (Fig. 3C). It is worth noting that autophagy was

upregulated through the $DGA1 \times N\text{-}lim$ factor, while ribosomes were (moderately) upregulated due to *DGA1* overexpression (Fig. 1). These changes are likely to affect protein half-lives and translation rates, modulating the protein concentration by means other than transcript levels. Nonetheless, the proteomics data supported the changes identified from the general linear model, as a hypergeometric gene-set enrichment analysis of highly correlated genes ($P < 0.01$) unveiled similar GO terms (Fig. 3D).

Control of fluxes. The combination of transcriptomics, proteomics, and binding-motif searches corroborates that amino acid biosynthesis and beta-oxidation are transcriptionally regulated, giving rise to the issue of whether these changes are also reflected in changes of metabolic fluxes. We therefore calculated metabolic fluxes using a genome-scale metabolic model by constraining measured exchange fluxes (Fig. S1; Table 1) and using random sampling of the solution space (18). This analysis was performed through four cross-comparisons: nitrogen versus carbon restriction in WT and *DGA1* strains and *DGA1* versus WT strains during nitrogen and carbon limitation. For each flux-gene pair, correlations were calculated from *Z* scores indicating the observed changes in metabolic flux and transcript and protein levels.

The number of strongly correlating fluxes differed drastically between the different comparisons (see Table S1 in the supplemental material). No large changes are expected in fluxes when phenotypic changes are only moderate. With only a few exchange fluxes constraining the intracellular fluxes, the random sampling approach gives a relatively high average relative standard deviation (RSD) for all flux-carrying reactions in the four conditions, and the fluxes therefore must change drastically for a significant *Z* score (typically >2) to occur. This approach is therefore likely to give an underrepresentation of fluxes that are correlated with changes in transcripts and protein levels.

The overall observation is that transcriptionally regulated fluxes are downregulated. In each comparison, the reference condition had a lower lipid yield, and increased lipid accumulation was not associated with an upregulation of lipid biosynthetic enzymes. The highest numbers of transcriptionally regulated fluxes were seen in the comparison of nitrogen limitation to carbon limitation with the *DGA1* overexpression strain, a result which can be expected from the changes in environmental conditions and lipid phenotype. In the comparison of the *DGA1* overexpression strain to the control strain during nitrogen limitation, only a few reactions were transcriptionally regulated. Interestingly, most transcriptionally regulated genes were those involved in leucine biosynthesis (Fig. 4A), correlating the observed transcriptional changes with not only protein levels but also changes in metabolic fluxes.

Metabolome analysis. To obtain further insight into whether flux changes are associated with changes in metabolite levels, we performed untargeted metabolomics analysis of intracellular and extracellular metabolites. Linear modeling was used to separate the changes in relative metabolite levels, and this analysis showed that overexpression of *DGA1* had limited effects on metabolite levels (Fig. S3 to S5). The main differences in extracellular metabolites were the excretion of sugars, sugar alcohols, and disaccharides under nitrogen restriction conditions. During batch stage, *Y. lipolytica* excretes disaccharides as an overflow metabolite when glucose is provided in excess, while the disaccharides are subsequently consumed upon glucose depletion (19). One of the metabolites excreted upon nitrogen restriction is the leucine biosynthetic pathway intermediate 2-isopropylmalate (IPM). However, the simultaneous overexpression of *DGA1* resulted in decreased excretion of this metabolite (Fig. 4B), even while the $DGA1 \times N\text{-}lim$ interaction did not significantly influence the excretion of the other carbohydrates (Fig. S3). This lack of IPM excretion is consistent with the transcriptional downregulation of the leucine biosynthetic pathway under the conditions with the highest lipid accumulation, likely through binding of a Leu3-like transcription factor to the leucine biosynthetic genes (cf. group 4 in Fig. 2A; Fig. 4A).

The changes in intracellular metabolite levels were more difficult to decipher. As seen with the external metabolites, nitrogen limitation resulted in increased levels of

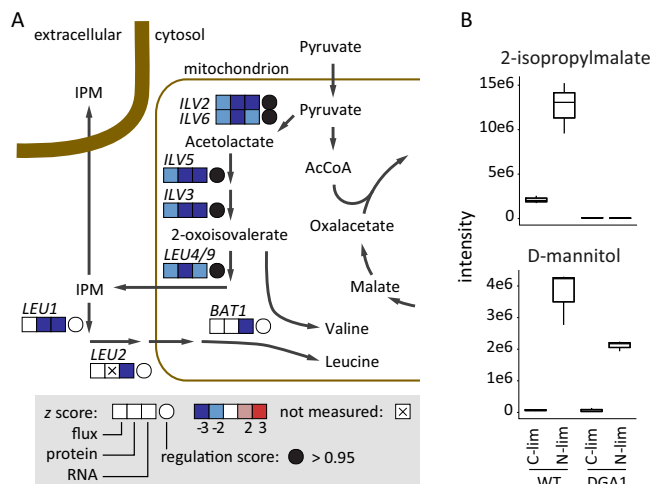

FIG 4 Regulation of *Y. lipolytica* metabolism. (A) Transcriptional downregulation of leucine biosynthesis. The boxes indicate z scores, incorporating both fold change and significance values. Regulation scores indicate correlations between all three levels and are calculated as detailed in Materials and Methods. (B) Relative intensity levels of two metabolites as measured by exometabolomics (also represented in Fig. S3 in the supplemental material). While most carbohydrates (e.g., D-mannitol) are excreted during nitrogen limitation in both WT and *DGA1* strains, 2-isopropylmalate (IPM) is no longer excreted when nitrogen limitation co-occurs with *DGA1* overexpression.

carbohydrates and organic acids such as glycolysis and tricarboxylic acid (TCA) cycle intermediates (Fig. S3). Additional *DGA1* overexpression increases the levels of many of the same metabolites. The increase in the levels of many amino acids resulting from *DGA1* × *N-lim* interaction, even though amino acid biosynthetic pathways were downregulated, is surprising. The levels of leucine and valine also increased, while branched-chain amino acid biosynthesis was strongly downregulated at the level of transcription. As autophagy is strongly upregulated through *DGA1* × *N-lim* interactions, it is possible that the increased amino acid levels were a consequence of protein degradation occurring through autophagy rather than as a consequence of increased *de novo* biosynthesis. These elevated levels could result in downregulation of amino acid biosynthesis, as particularly seen for the branched-chain amino acid biosynthesis. A cell undergoing nitrogen limitation would potentially benefit from increased expression of branched-chain amino acid transaminases (BCAT), as a means of shuffling amino groups between the products of protein degradation. Nonetheless, BCAT genes *BAT1* and *BAT2* respond differently to nitrogen limitation (Fig. S6). While cytosolic *BAT2* is upregulated irrespective of whether or not *DGA1* overexpression is present, mitochondrial *BAT1* instead shows an expression response similar to that seen with, e.g., leucine biosynthesis. This suggests that the primary function of *BAT1* is *de novo* biosynthesis, while *BAT2* is instead involved in reshuffling amino groups within the cytosolic branched-chain amino acid pool. The observed amino acid levels, however, do not provide a clear picture supporting this remodeling of amino acid metabolism.

DISCUSSION

Lipid accumulation in *Y. lipolytica* is a complex trait where both genetic and environmental factors have influence. In this study, we observed clear phenotypical changes on the level of lipid accumulation, induced by both genetic factors and environmental factors, and we have linked these phenotypic changes to regulatory changes.

As postulated previously, lipid accumulation is not achieved through transcriptional regulation of lipid biosynthetic enzymes (6, 7, 11), while it is conceivable that post-translational modifications play a role (6). Instead, nitrogen limitation induces a transcriptional downregulation of beta-oxidation, thereby positively affecting the lipid levels. We found that this downregulation may be regulated by Mig1 (Fig. 2B), and, as

FIG 5 Schematic overview of responses to either nitrogen limitation or $DGA1 \times N\text{-}lim$ interaction. Potential regulatory networks are drawn, guided by changes in motif enrichments and in metabolite and expression levels. Leucine activates TORC1 only as a response to $DGA1 \times N\text{-}lim$ interaction, as leucine levels are not increased in the presence of nitrogen limitation alone. Gln3 and autophagy are seemingly not repressed by TORC1 as a response to $DGA1 \times N\text{-}lim$ interaction. Leu3 either represses or activates expression of leucine biosynthesis, depending on IPM levels. While TORC1 is repressed upon nitrogen limitation, its activity is seemingly modulated upon simultaneous $DGA1$ overexpression, likely due to the sensing of increased leucine levels, mediated by leucyl-tRNA synthetase.

beta-oxidation is upregulated in *snf1Δ* and *mig1Δ* strains (8, 9), it is likely that binding of Mig1 represses expression of beta-oxidation genes. ATP-citrate lyase (ACL), malic enzyme, oxoglutarate dehydrogenase, and glycerol 3-phosphate dehydrogenase genes are also upregulated in a *mig1Δ* strain, and most of these genes were found here to be downregulated in nitrogen-limited chemostats. Surprisingly, transcripts of the two ACL subunits were significantly downregulated whereas protein levels were substantially upregulated, indicating complex regulation of this protein.

In our multifactorial analysis, we found a clear downregulation of amino acid biosynthetic pathways due to an interaction between $DGA1$ overexpression and nitrogen restriction. This downregulation was not an effect of nitrogen limitation by itself, as observed previously (11), but was observed only as an interaction of nitrogen limitation with $DGA1$ overexpression (see Fig. S2 in the supplemental material). The pathway most strongly affected by the $DGA1 \times N\text{-}lim$ interaction was leucine biosynthesis, supported not only by RNAseq data but also by proteomics data, as well as by estimation of fluxes and metabolomics data.

The leucine biosynthetic genes are furthermore regulated by a *S. cerevisiae* Leu3-like transcription factor. In *S. cerevisiae*, Leu3 inhibits the expression of the *ILV* and *LEU* genes of branched-chain amino acid biosynthesis, except under conditions of isopropylmalate (IPM) accumulation, which is indicative of leucine depletion (20). From the combined data, a picture emerges where IPM plays an important role in the regulatory responses to different factors, where two different regulatory states both result in lipid accumulation (Fig. 5). Nitrogen limitation by itself enhances lipid accumulation by increasing the flux through acetyl-CoA. Nitrogen limitation also results in repression of TORC1, and it has been reported that TORC1 inhibition by sirolimus increases lipid accumulation (4). Among other effects, TORC1 inhibition results in activation of Gln3, Gcn4, and Leu3 (Fig. 5). This is apparent from searches of the binding motifs, where nitrogen limitation makes a strong positive contribution to the expression levels of group 2 and group 4, which are enriched for nitrogen utilization and amino acid biosynthesis (Fig. 2). Upon nitrogen limitation, IPM levels increase (Fig. S3), and the interaction of IPM with Leu3 further activates the expression of *ILV* and *LEU* genes (shown for *ILV3* in Fig. 1C). The interaction of $DGA1$ overexpression and nitrogen limitation has a very different regulatory effect (Fig. 5). How this behavior is invoked remains unclear, but it is conceivable that $DGA1$ overexpression enforced a larger redistribution of the pyruvate flux, toward lipid instead of leucine biosynthesis. This reduced the level of IPM (Fig. S3), and Leu3 then acted as a repressor of *ILV* and *LEU* genes (Fig. 1C). Simultaneously, leucine levels increased (Fig. S3), and an additional regulatory pathway then came into play. In *S. cerevisiae*, leucyl-tRNA synthetase (LRS) can activate TORC1 by phosphorylation through interactions with Gtr1 in a leucine-dependent manner (21). Furthermore, supplementation of more leucine to a leucine-

auxotrophic *Y. lipolytica* resulted in higher lipid accumulation (4). The increased leucine level is potentially activating TORC1, and while nitrogen limitation continues to inhibit TORC1 activity, it seems that the leucine signal is stronger. The activated TORC1 then represses Gcn4 and Leu3, an effect which presents itself in the form of strong down-regulation of various amino acid biosynthetic pathways (Fig. 1B), effectively causing a positive-feedback loop. While TORC1 is also able to repress Gln3 and autophagy, it seems that this does not happen through the DGA1 \times N-lim interaction but potentially through an alternative mechanism.

While nitrogen limitation, or sirolimus treatment, represses TORC1 and induces lipid accumulation, we observed the highest lipid accumulation when TORC1 activity was modulated by leucine levels. It seems that this regulatory behavior is active only after a certain lipid accumulation threshold is reached, as only the interaction of DGA1 overexpression and nitrogen limitation unveiled this regulation.

Our results indicate the involvement of leucine biosynthesis in the seemingly unrelated phenotype of lipid accumulation in *Y. lipolytica*. Previously, leucine has been implicated in other complex phenotypes, e.g., ethanol tolerance in *S. cerevisiae* (22). Jointly, these findings show that leucine functions as a key metabolic node in diverse phenotypes across yeast species.

MATERIALS AND METHODS

Yeast strains, cultivations, and lipid analysis. The *Y. lipolytica* strains used in this study were DGA1 overexpression strain MTYL053 and the corresponding MTYL038 control strain, both of which are prototrophic strains derived from Po1g as described in reference 2. Chemostat cultivations were performed at a dilution rate of 0.05 h^{-1} at 30°C in 1.2-liter bioreactors (DASGIP, Jülich, Germany) with a working volume of 750 ml at pH 3.5, controlled with 2 M KOH. A stirring rate of 600 rpm and an airflow rate of 1 vessel volume per min (vvm) kept the concentration of dissolved oxygen above 30%. For carbon restriction experiments, 1 liter of medium contained 5 g glucose, 5 g $(\text{NH}_4)_2\text{SO}_4$, 3 g KH_2PO_4 , 0.5 g $\text{MgSO}_4 \cdot 7 \text{H}_2\text{O}$, vitamins and trace metal solutions (23), and 125 μl Antifoam 204 (Sigma-Aldrich, St. Louis, MO, USA). A similar medium was used for nitrogen restriction experiments where the glucose level was increased to 25 g and the $(\text{NH}_4)_2\text{SO}_4$ level was decreased to 0.5 g while the SO_4 levels were kept constant by adding 5.96 g $\text{K}_2\text{SO}_4 \cdot \text{CO}_2$, and residual O_2 and residual O_2 levels in the exhaust gas were measured by the use of an online gas analyzer (DASGIP). Samples for various analyses were rapidly taken at the steady state, defined as stable CO_2 and O_2 outflow and optical density. Lipid content and fatty acid composition were analyzed using gas chromatography-mass spectrometry (GC-MS) and liquid chromatography-charged aerosol detection (LC-CAD), respectively, as described previously (24, 25), and data were normalized to dry cell weight. Fermentation and lipid and fatty acid data for the DGA1 strain were obtained from reference 11.

RNAseq analysis. For RNA analysis, samples were rapidly taken from steady-state chemostats and stored at -80°C . Total RNA was extracted using Trizol (Invitrogen, Carlsbad, CA) and a FastPrep homogenizer (MP Biomedicals, Santa Ana, CA, USA) with 1-mm-diameter silica beads. Further RNA preparation and RNAseq were performed by SciLifeLab in Uppsala, Sweden, on their IonTorrent platform. Data from the control strain have been deposited at ArrayExpress (<http://www.ebi.ac.uk/arrayexpress/experiments/E-MTAB-5284/>), while data for the DGA1 strain are available from <http://www.ebi.ac.uk/arrayexpress/experiments/E-MTAB-3837/>. RNAseq reads were mapped to the *Y. lipolytica* CLIB122 reference genome with Bowtie 2.1.0 (26) and counted with HTseq (27). Transcripts with at least 3 libraries with more than 1 cpm were normalized using the trimmed means of M values (TMM) (28) and transformed using voom (29). Differential gene expression was analyzed following the following general linear model: $\text{expr} = \beta_0 + \beta_{\text{Nlim}}X_{\text{Nlim}} + \beta_{\text{DGA}}X_{\text{DGA}} + \beta_{\text{DGA}\cdot\text{Nlim}}X_{\text{DGA}\cdot\text{Nlim}} + \varepsilon$. Log-transformed count data and differential expression analysis data are available at the following doi: [10.6084/m9.figshare.4990394](https://doi.org/10.6084/m9.figshare.4990394). For studies of correlation between RNA, protein, and fluxes, normalized and log-transformed counts were used, while correlation scores were calculated according to a previously described method (18).

Gene-set analysis and motif searching. Gene-set analysis was performed using the Piano package (30) for R. GO terms were obtained from reference 11, while those sets corresponding to “cellular localization” and gene sets with fewer than 5 or more than 500 genes were discarded. Consensus gene-set analysis was performed in a routine manner, and a rank score cutoff value of 1 was used for visualization. For motif searching, genes with an adjusted *P* value of <0.01 were manually sorted by ranking the coefficients of the three experimental factors in the general linear model (see Fig. 2A). Motif searches were performed using DREME (15), with the genes in each cluster as primary sequences, all other genes as control sequences, and an *E* value cutoff value of 10^{-3} . Obtained motifs were queried for similarity to *S. cerevisiae* motifs using Tomtom (31).

Proteomics. Total cell protein was obtained via a chloroform/methanol-water extraction method that provides discrete protein, metabolite, and lipid fractions (32) and was digested into peptides as described in reference 6. Label-free quantitative proteomics data were obtained using the accurate mass and time (AMT) tag approach (reviewed in reference 16). Briefly, aliquots of each sample were pooled equally, fractionated into 48 fractions, and analyzed by LC-tandem MS (LC-MS/MS) to establish an AMT tag database of identified peptides and proteins, also described in reference 6. Subsequently, each sample

was analyzed separately without fractionation, the masses and normalized LC retention times of detected peptides were compared to entries in the AMT tag database for identification, and peptides were quantified using the integrated LC-MS peak as also described in reference 6. Quality control processing removed peptides with an insufficient amount of data across all samples (33), while peptide abundance values within a sample were normalized using a rank invariant peptide selection approach (33). Protein level abundances were estimated using a standard reference-based methodology, R-Rollup (34). For further differential expression analysis and to facilitate comparison with transcript counts, protein counts were normalized and transformed using the same normalization and transformation methods as are detailed for RNAseq data above. Log-transformed count data and differential expression analysis data are available at the following doi: [10.6084/m9.figshare.4990394](https://doi.org/10.6084/m9.figshare.4990394).

Metabolomics. For the measurements of intracellular metabolites, 20 ml of cell suspension was passed through a 0.5 μm nylon filter and was washed with 5 ml 150 mM ammonium bicarbonate. The cells were quenched with 2 ml of cold chloroform/methanol (2:1 [vol/vol]) and 0.5 ml of H_2O containing 0.72 mM anthranilate as an internal standard. Cell debris was pelleted at $15,000 \times g$ for 10 min, and the upper phase of polar metabolites was collected and snap-frozen in liquid nitrogen before sample analysis. Extracellular metabolites were collected through a similar protocol of phase separation of the cell-free spent medium after filtration. The extracted metabolites were analyzed as previously reported (19). Briefly, extracted metabolites were completely dried *in vacuo* and subjected to chemical derivatization for GC-MS analysis. The collected data were processed, and experimental metabolite spectra and retention indices were matched to entries in an in-house version of the Agilent Fiehn metabolomics library, as well as to the NIST14 GC-MS library (35, 36) or by using spectra alone (denoted "NIST").

Genome-scale metabolic modeling. Metabolic fluxes were estimated using *iYall4*, a genome-scale model of *Y. lipolytica* metabolism (11). For each experimental condition, the model was adjusted to match the lipid and fatty acid measurements (represented in the biomass composition) and the relevant exchange fluxes. For determining flux ranges, the measured exchange fluxes and growth rate were allowed to vary within 1 standard deviation from the average measured values, while non-growth-associated maintenance (NGAM) energy was allowed to vary 5% around its maximum value, determined by setting the NGAM energy parameter as the objective function. Subsequent random sampling of these models delivered the Z scores, which were correlated with RNA expression data (18). The condition-specific models are available at the following doi: [10.6084/m9.figshare.4990394](https://doi.org/10.6084/m9.figshare.4990394).

ACKNOWLEDGMENTS

Computations were performed on resources at the Chalmers Centre for Computational Science and Engineering (C3SE) provided by the Swedish National Infrastructure for Computing (SNIC). Sequencing support was provided by the Science for Life Laboratory (SciLifeLab), National Genomics Infrastructure (NGI), and UPPMAX. We acknowledge Petri-Jaan Lahtvee, Michael Gossing, and Benjamin Sanchez for valuable contributions to the manuscript.

This work was funded by the Genome Science Program (GSP), Office of Biological and Environmental Research (OBER), U.S. Department of Energy (DOE) under award number DE-SC0008744; the GSP-funded Pan-omics Program at the Pacific Northwest National Laboratory (PNNL); and the Novo Nordisk Foundation and the Knut and Alice Wallenberg Foundation. The Environmental Molecular Sciences Laboratory at PNNL is operated by Battelle for the DOE under contract DE-AC05-76RLO 1830.
